ABSTRACT

We present mid-infrared (8–33 μm) observations of the binary L5-Trojan system (617) Patroclus-Menoetius before, during, and after two shadowing events, using the Infrared Spectrograph (IRS) on board the Spitzer Space Telescope. For the first time, we effectively observe changes in asteroid surface temperature in real time, allowing the thermal inertia to be determined very directly. A new detailed binary thermophysical model is presented which accounts for the system’s known mutual orbit, arbitrary component shapes, and thermal conduction in the presence of eclipses.

We obtain two local thermal-inertia values, representative of the respective shadowed areas: $21 \pm 14 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ and $6.4 \pm 1.6 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$. The average thermal inertia is estimated to be $20 \pm 15 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$, potentially with significant surface heterogeneity. This first thermal-inertia measurement for a Trojan asteroid indicates a surface covered in fine regolith. Independently, we establish the presence of fine-grained ($< \text{a few } \mu\text{m}$) silicates on the surface, based on emissivity features near 10 and 20 μm similar to those previously found on other Trojans.

We also report V -band observations and report a lightcurve with complete rotational coverage. The lightcurve has a low amplitude of $0.070 \pm 0.005 \text{ mag}$ peak-to-peak, implying a roughly spherical shape for both components, and is single-periodic with a period ($103.02 \pm 0.40 \text{ h}$) equal to the period of the mutual orbit, indicating that the system is fully synchronized.

The diameters of Patroclus and Menoetius are 106 ± 11 and $98 \pm 10 \text{ km}$, respectively, in agreement with previous findings. Taken together with the system’s known total mass, this implies a bulk mass density of $1.08 \pm 0.33 \text{ g cm}^{-3}$,

significantly below the mass density of L4-Trojan asteroid (624) Hektor and suggesting a bulk composition dominated by water ice.

All known physical properties of Patroclus, arguably the best studied Trojan asteroid, are consistent with those expected in icy objects with devolatilized surface (extinct comets), consistent with what might be implied by recent dynamical modeling in the framework of the Nice Model.

1 Introduction

1.1 *Thermal inertia*

Thermal inertia is a measure of the resistance to changes in surface temperature. A hypothetical zero-thermal-inertia asteroid would be in instantaneous thermal equilibrium with insolation and display a prominent sub-solar temperature peak. In general, thermal inertia causes the surface temperature distribution to have reduced contrast and be asymmetric with respect to the sub-solar point, with the maximum shifted to the afternoon side. The influence of thermal inertia on the temperature distribution is maximum when the spin vector is perpendicular to the solar direction and zero if it points towards the Sun.

Thermal inertia is defined as $\Gamma = \sqrt{\kappa\rho c}$, with thermal conductivity κ , surface bulk mass density ρ , and heat capacity c . The range in which ρ and c can plausibly vary is much more restricted than for κ , which can vary by several orders of magnitude (see, e.g., Mueller, 2007, Sect. 3.2.2.b for a detailed discussion).

Examples of low and high thermal inertia cases would be a dusty, thermally insulating surface such as that of the Moon, and a rocky, thermally conductive surface, respectively. It is qualitatively clear that for fine-grained regolith (where the typical grain size is not large compared to the penetration depth of the heat wave), thermal conductivity and thermal inertia decrease with decreasing grain size. This is confirmed by laboratory studies under a simulated Martian atmosphere (Presley and Christensen, 1997), but no quantitative data are available for vacuum conditions.

The thermal inertia of the largest few main-belt asteroids is known to be low and indicative of a surface covered in fine regolith (e.g. Spencer, 1990; Müller and Lagerros, 1998). It was recently found that the thermal inertia of $D < 100$ km main-belt asteroids and near-Earth asteroids is increased relative to large main-belt asteroids, more so for smaller objects, but that it stays significantly below values expected for bare-rock surfaces (Mueller, 2007; Delbo' et al., 2007; Delbo' and Tanga, 2009). No quantitative measurements of the thermal inertia of Trojans have been published.

The thermal inertia of asteroids is typically determined indirectly, from multi-filter observations in the challenging mid-infrared wavelength range at widely-spaced phase angles, such that the sub-observer point is located at different rotational phases (“local times”) and information on the diurnal temperature distribution can be obtained. Depending on the apparent target motion, this may require observations stretched out over a significant time span.

Eclipse-induced shadowing, on the other hand, offers an opportunity to determine the thermal inertia more directly, by monitoring the shadowing-induced cooling and the later warming up. This technique was pioneered by Pettit and Nicholson (1930), who determined the thermal inertia of the Moon for the first time from thermal observations during a total lunar eclipse. Morrison and Cruikshank (1973) report observations of the Galilean satellites as they were eclipsed by Jupiter; Neugebauer et al. (2005) report observations of Iapetus during eclipses by Saturn’s rings; eclipse observations of Saturn’s satellites using the Cassini spacecraft are ongoing (Pearl et al., 2008).

Asteroids are not frequently shadowed by planets. Binary asteroids, however, can undergo mutual eclipses, during which one component shadows the other.

Recent progress now allows mutual eclipse events in an increasing number of binary asteroid systems to be reliably predicted.

1.2 Binary Trojan asteroid Patroclus

Our target, (617) Patroclus, is one of the few known binary systems in the population of Trojan asteroids, which are in 1:1 orbital resonance with Jupiter, close to the Lagrangian points L4 and L5. Trojan orbits are stable over most of the age of the Solar System (Levison et al., 1997). Their origin is currently under debate: While they were long believed to have formed near their present position (see, e.g., Marzari et al., 2002), Morbidelli et al. (2005, 2009) argue in the context of the ‘Nice model’ that Trojans were captured by Jupiter during a chaotic phase in the early Solar System, which was caused by a mean-motion resonance between Jupiter and Saturn. In this model, Trojans share a volatile-rich parent population with comets and Trans-Neptunian Objects but have spent parts of their lifetime at relatively small heliocentric distances (potentially enough to leave their surface devolatilized) before being trapped in their current orbits.

Trojans have generally low albedos of $p_V \sim 0.04$ and virtually featureless, highly reddened reflection spectra in the visible and near-IR wavelength ranges; in both respects, they resemble cometary nuclei (see Dotto et al., 2008, for a recent review). Mid-IR spectra of three Trojans have revealed the presence of fine-grained silicates on the surfaces (Emery et al., 2006). Trojans smaller than some 70 km in diameter appear to be collisional fragments, while larger bodies appear to be primordial “accretion survivors,” i.e. bodies whose current form and internal structure have remained unchanged since the time of their

formation (Binzel and Sauter, 1992; Jewitt et al., 2000).

(617) Patroclus was discovered in October 1906 by August Kopff. Following (588) Achilles, which had been discovered in February 1906, Patroclus was the second known Trojan and the first known object in the L5 swarm. With an absolute magnitude in the HG system (V magnitude normalized to a standard geometry; see *Bowell et al., 1989*) of $H = 8.19$, Patroclus is among the largest Trojans. Based on IRAS observations, *Tedesco et al. (2002)* report a diameter of $D = 140.9 \pm 4.7$ km, corresponding to a geometric albedo of $p_V = 0.047 \pm 0.003$ (see eqn. 1 below). *Fernández et al. (2003)* obtained Keck 12.5 μm observations of Patroclus and derived a diameter of 166.0 ± 4.8 km ($p_V = 0.034 \pm 0.004$). Note that the quoted diameters are area-equivalent diameters D_A of the system as a whole. D_A is related to the components' diameters, D_1 and D_2 , through $D_A^2 = D_1^2 + D_2^2$.

Patroclus was found to be binary by *Merline et al. (2001)*. The system's mutual orbit was first determined by *Marchis et al. (2006a)* based on spatially resolved adaptive-optics observations. Subsequently the secondary component was christened Menoetius. *Berthier et al. (2007)* provide an updated orbit model (consistent with that by *Marchis et al.*) based on additional spatially non-resolved optical photometry measurements during mutual events. The *Berthier et al.* model is used throughout this paper. The system's mutual orbit is purely Keplerian (no precession) and circular (eccentricity ≤ 0.001). The center-to-center separation of the two components is 654 ± 36 km, corresponding to a maximum angular separation around $0.2''$. The J2000 ecliptic coordinates of the spin-pole orientation are $\lambda = 241.37 \pm 0.33^\circ$, $\beta = -57.35 \pm 0.36^\circ$, the orbital period equals 102.94 ± 0.11 h. This orbit model reproduces the adaptive-optics observations and the morphology of eclipse-

induced lightcurves very well. Predicted and measured eclipse timing may differ by up to a few hours (= a few percent of the orbital period). Work is under way to resolve these slight timing differences. No discernible change in the model’s spin-axis orientation is expected to result from this.

Marchis et al. (2006a) report a component-to-component magnitude difference of ~ 0.17 mag; the same magnitude difference was found for two filters centered at 1.6 and 2.2 μm , respectively, which Marchis et al. take as an indication of similar surface composition. Assuming identical albedo, the corresponding diameter ratio is $D_1/D_2 \sim 1.082$.

Through Newton’s parametrization of Kepler’s Third Law, the orbital parameters imply a total system mass of $(1.20 \pm 0.20) \times 10^{18}$ kg. Marchis et al. used the size estimate by Fernández et al. (2003) to infer a bulk mass density of only $0.8^{+0.2}_{-0.1}$ g cm $^{-3}$, compatible with a composition dominated by water ice and moderate porosity. Berthier et al. determined the components’ diameters independently, from eclipse timing, to be $D_1 = 112 \pm 16$ km and $D_2 = 103 \pm 15$ km, and a bulk mass density of $0.90^{+0.19}_{-0.33}$ g cm $^{-3}$.

1.3 Work presented in this paper

The Marchis et al. (2006a) orbit model allowed a series of mutual events to be predicted, including two shadowing events in June 2006 which we observed using the Spitzer Space Telescope. We observed the system’s thermal emission before, during, and after the events (see sect. 3). Although the system was not spatially resolved, Spitzer’s high sensitivity allowed us to effectively observe the eclipse-induced cooling and later warming up of shadowed surface elements

Fig. 1. Composite visible lightcurve from our April 1996 observations. Data points at rotational phases 0.0–0.2 are repeated at 1.0–1.2 for clarity. Synthetic lightcurves are superimposed, from a 2nd order Fourier fit to the data (solid line) and from a 1.07:1.0:1.0 ellipsoid model (dash-dotted line). See text for details.

in real time. *No such observations have been performed before. We present the first direct measurement of the thermal inertia of an asteroid.* A new thermophysical model for eclipsing binary asteroids has been developed to facilitate the data analysis (see sect. 5).

We also obtained Patroclus’ mid-IR emissivity spectrum from our Spitzer data (see sect. 4), and its visible lightcurve from ground-based observations (see sect. 2).

2 Visible lightcurve observations

We observed (617) Patroclus using the 61 cm Bochum Telescope at the European Southern Observatory in La Silla during 10 nights in April 1996; see table 1 for observational details. The observations were performed in the Johnson

V band with the DLR MKII camera, using a Tektronix 1k x 1k CCD.

Differential photometry was performed against field stars, which were subsequently absolutely calibrated against observations of standard stars present in near-by fields. Fluxes were extracted through synthetic aperture photometry,

using the AstPhot program (Mottola et al., 1995). The typical 1σ uncertainties in the differential photometry were well below 0.01 mag; the typical absolute photometric errors were of the order of 0.02 mag RMS.

The synodic rotation period was determined by using the Fourier analysis technique described by Harris and Lupishko (1989). This technique seeks the period that, in the least-squares sense, best fits the observations. In order to remove the effects of changing brightness on subsequent nights due to solar phase effects, or to uncertainties in the nightly absolute photometric calibrations, the method enables grouping of observations (with one group usually comprising observations from one night) and estimates magnitude shifts for each group that minimize the residuals. In our case it became soon apparent that the time spanned by each night of observation was much shorter than the rotation period of Patroclus. As a consequence, when folded into a composite, single-night data stretches would only sporadically overlap with each other, thereby providing little constraint for the solution of the single-night magnitude shifts. For this reason, whenever possible, we grouped the observations in sets of two consecutive nights, which resulted in a total of 6 groups with a good mutual overlap. Subsequently, the magnitudes within each data set were reduced to a reference phase angle (chosen as the phase angle of the observations closest to the average phase angle in each data subset) by using the HG model (Bowell et al., 1989) and a G value of 0.12. Because the phase angle change rate at the time of the observations was only of the order of 0.1° per day, even a very large deviation of the assumed G value from the actual one would result in a negligible error.

The data are well described with a Fourier polynomial of 2nd order. The resulting best-fit synodic period is $P_{syn} = 103.02 \pm 0.40$ h. P_{syn} agrees with

the Berthier et al. (2007) result of 102.94 ± 0.11 h for the period of the mutual orbit, i.e. the rotational variability and the mutual orbit are synchronized. See Fig. 1 for a composite lightcurve in which the single-night observations are folded with the lightcurve period, along with the Fourier fit. The lightcurve amplitude is found to be 0.070 ± 0.005 mag peak-to-peak.

To our knowledge, no complete lightcurve of Patroclus has been published previously, although it was known to have a long period and low amplitude (Angeli et al., 1999). No signs of multiple periodicity (which might be expected in a binary system) are discernible in our data. This implies that no mutual events occurred at the time of our observations (consistent with the Berthier et al., 2007, model) and indicates a fully synchronized binary system. The small lightcurve amplitude implies that both components are nearly spherical in shape. While the data do not allow an unambiguous shape model to be determined, the observed lightcurve can be reproduced reasonably well assuming two slightly prolate spheroids with axial ratios 1.07:1:1, a realistic photometric function, and the Berthier et al. spin axis (see Fig. 1).

3 Spitzer observations

Patroclus was observed using the InfraRed Spectrograph (IRS; Houck et al., 2004) on board the Spitzer Space Telescope (Werner et al., 2004). IRS was used in low-resolution spectroscopy mode using the modules SL1, LL1, and LL2 to obtain flux-calibrated spectra in the nominal wavelength range 7.4–38 μm at a relative spectral resolution $\lambda/\Delta\lambda$ between 64 and 128. The observed flux is practically purely thermal; the reflected component is negligible at these wavelengths (Emery et al., 2006). The angular separation of Patroclus and

Table 2

Observing geometry at the epoch of our observations. The heliocentric and Spitzer-centric coordinates are longitude and latitude in J2000 ecliptic coordinates. All values are constant during our observations to ± 1 in the last quoted digit or better. The absolute visible magnitude equals $H = 8.19$ (quoted after Tedesco et al., 2002); the slope parameter of the phase curve is assumed to be $G = 0.15$.

Event:	1	2
heliocentric distance r	5.947 AU	5.947 AU

Menoetius does not exceed $0.2''$ while the IRS pixel scale is $1.8''$ or coarser; the system was not spatially resolved.

Time-resolved observations were obtained during two consecutive mutual events in June 2006, referred to as events 1 and 2 in the following. In event 1, Patroclus shadowed Menoetius, and vice versa in event 2. The diameter ratio is only ~ 1.1 and the mutual orbit is circular, hence the two events produced very similar observable effects. Both events lasted about 4 h and were pure shadowing events (the line of sight toward Spitzer was never obstructed). Thermal emission from the shadowed surface areas therefore contributes to the observable flux.

A total of 18 thermal-infrared spectra of Patroclus were obtained, nine per

Table 3

event, referred to as 1.0–1.8 and 2.0–2.8, respectively. See table 2 for the observing geometry during the events. Observation start times are given in table 3; each observation lasted ~ 6 min. As can be seen in Fig. 2, our observations provide good temporal coverage of both events and their aftermath. The Marchis et al. (2006a) orbit model was used to predict the time of the events several months ahead. Observations 1.0 and 2.0 were performed well before the start of the events, in order to establish a flux baseline.

Fig. 2. Geometry of the system’s mutual orbit during our Spitzer observations as seen from Spitzer, generated using the Berthier et al. (2007) orbit model. Each frame corresponds to one of our observations 1.1–1.8 (top two rows) and 2.1–2.8 (lower two rows), see table 3. Observations 1.0 and 2.0 are not plotted; at this scale, only one component would be displayed. Each frame is centered on Patroclus; its angular diameter is ~ 12.4 milli arcsec. During event 1, Menoetius is shadowed by Patroclus; and vice versa during event 2. The line of sight toward Spitzer was never obstructed. The event timing was shifted somewhat relative to the Berthier et al. prediction (within the uncertainties) to match the best-fit eclipse timing found in sect. 7.2. The system is eclipsed during observations 1.1–1.4 and 2.3–2.6, respectively.

To prevent flux from ‘spilling over’ the edge of the slit, IRS spectroscopy targets must be accurately centered into the slit. The projected width of the LL slit is above $10''$, while that of the SL1 slit is $3.7''$, comparable to the width of the point-spread function (PSF) in the respective wavelength range. For comparison: the pixel scale is $1.8 \mu\text{m}$ in the SL modules and $5.1 \mu\text{m}$ in the LL modules. “Blind” telescope pointings have a 1σ -accuracy of $0.5''$ and are

therefore adequate to center sources of well known position (such as Patroclus) in the wide LL slits but risk placing a significant fraction of the PSF outside the SL1 slit. Instead, small “spectral maps” were created for the SL1 observations, with three small steps perpendicular to the slit, each offset by 2'' (roughly half the slit width). This allowed us to estimate the target offset from the slit center and to correct for the effects thereof in the data analysis (see below).

The usual “nod” strategy was used, i.e. the target was placed at about 33 and 66 % of the slit length in each module in order to enable subtractive correction for diffuse background emission (“sky background”).

The data obtained were reduced using the methods described in Emery et al. (2006, sect. 3). Briefly, the Spitzer Science Center (SSC) receives the data from the telescope and runs it through a reduction pipeline that converts raw data into 2-D spectral flux images (electrons/s) while flagging bad pixels, correcting known stray light artifacts, and performing flat field corrections. The output is termed Basic Calibrated Data (BCD), which is described in detail in the IRS Data Handbook (<http://ssc.spitzer.caltech.edu/irs/dh/>). The data presented in this paper result from the BCD pipeline version S16.1.0.

The BCD files contain background emission, mostly from the zodiacal cloud, which is removed by subtracting the two nod positions from one another for each observation. Extraction of the data to 1-D spectra essentially follows that of ground-based spectral data, where the object is identified in each row and the dispersion mapped across the chip. The signal (e^-/s at this point) is the sum of the pixels within the chosen extraction width at each wavelength. Fractional pixels are included assuming the flux is evenly distributed across

the individual pixel. The SSC provides a wavelength map of the chip for each spectral order. Since Spitzer is diffraction limited, the PSF, and therefore optimal extraction width, varies with wavelength. We use the same extraction width as recommended by the SSC: $\sim 2 \times \text{FWHM}$ (14.4", 21.68", and 36.58" at 12 μm , 16 μm , and 27 μm , respectively) and varying linearly with wavelength. Because of the varying PSF width and several other artifacts, the extracted spectral shape for each order is known to be slightly incorrect. The SSC corrects ("tunes") the final spectral shape using a 5th order polynomial fit to the ratio of stellar calibrator observations to models of their spectral shape (Decin et al., 2004). These ratios are also used for final flux calibration (i.e., converting from e^-/s to Jy). We perform basically the same procedure, with the exception that we use different calibrator stars, and we do not fit a polynomial, but rather apply the average ratio of the stars to the model directly. For the data presented here, we used δ UMi, HR 2194, and HR 7891 for the SL modules and HD173511, δ UMi, and HR 7341 for the LL modules. The different orders (SL1, LL2, and LL1) overlap slightly, and we scale the different orders relative to each other using these overlap regions. We then rescale the entire spectrum to the mean of the individual scale factors. The different low resolution orders generally agree within $< 7 \%$.

Observations at some wavelengths are compromised by defective detector pixels and are disregarded in the following, e.g. all wavelengths above 33 μm . Systematic flux uncertainties due to, e.g., the residual effect of source mis-centering or uncertainties in the absolute flux calibration are estimated to be 3 % and added to the statistical uncertainty. The total flux uncertainty is dominated by the systematic uncertainty except for the low fluxes on the Wien slope at the shortest wavelengths. Final fluxes are provided in the On-

Fig. 3. Top: Ratio of two measured thermal spectra relative to pre-event measurement 1.0. Observation 1.2 (bottom) was taken during the eclipse, observation 1.7 (top) in the aftermath. line Supplementary Material. See Fig. 3 for a plot of representative flux ratios during event 1.

4 Emissivity features

The observed spectra contain slight spectral features due to silicates within the wavelength ranges 10–12 μm and 18–22 μm . Emissivity spectra are calculated by dividing the measured flux spectrum by the modeled thermal continuum. Since we are not interested in smooth spectral slopes but in discrete features, the specific choice of model continuum is uncritical at this point. We see no reliable spectral variation among the 18 observations and therefore show the grand average.

Our final emissivity spectrum result for the Patroclus system is shown in Fig. 4 and compared to that of the Trojan asteroid (624) Hektor (Emery et al., 2006). Features near 10 and 20 μm are clearly visible; small scale (single channel) structure in the Patroclus spectra, e.g. near 25 μm , are residual calibration artifacts.

Emery et al. conclude that the features near 10 and 20 μm in Hektor (and two other Trojan asteroids) are due to the presence of fine-grained ($< \text{few } \mu\text{m}$) silicates, likely in either a very under-dense ("fairy-castle") structure or embedded in a matrix material that is fairly transparent at these wavelengths (e.g., certain organic materials). Since the broad emissivity peaks in the Patroclus spectrum occur at the same wavelengths and with very similar shapes to those in the spectrum of Hektor, it is reasonable to infer similar mineralogy for the surface of Patroclus. The features, particularly the one near 10 μm , are more subdued in the spectrum of Patroclus than that of Hektor (or the other two Trojans presented in Emery et al., 2006). This is most likely due to differences in grain size or packing state of the surface, two factors which

Fig. 4. Emissivity spectra of Patroclus (see text) and Hektor (Emery et al., 2006).

Spectra are shifted vertically for clarity.

strongly affect the shape of spectra at these wavelengths, but could also imply different mixing ratios of silicates to opaque material.

In order to avoid biases in thermal modeling, the wavelengths at which these features occur (10–12 μm and 18–22 μm) were disregarded in the thermal analysis, leaving 178 data points per observation.

5 Thermophysical modeling

Analyzing thermal-infrared observations of asteroids requires a thermal model to calculate expected fluxes. To this end, the temperature distribution is calculated based on the observing geometry and assumed physical properties, then the observable model flux is calculated by integrating the Planck function over the visible surface.

Thermal fluxes depend on a number of physical properties, among them the effective diameter D , geometric albedo p_V , shape, thermal inertia Γ , spin pe-

riod P , spin-axis orientation, and amount of surface roughness. Typically, the absolute visible magnitude H is known, such that p_V and D are linked through (see Pravec and Harris, 2007, Appendix A, and references therein)

$$D = 10^{-H/5} \frac{1329 \text{ km}}{\sqrt{p_V}}, \quad (1)$$

reducing the number of free parameters by one.

The surface temperature distribution is governed by Γ (together with the spin rate): An object with zero thermal inertia (or vanishing spin rate) would display a prominent temperature difference between the hot sub-solar point and the $T = 0$ night side, whereas increasing Γ (or spin rate) shifts the temperature maximum toward the afternoon side and, for observations at low phase angles, reduces the apparent color temperature, since solar energy is stored and re-emitted at night.

Surface roughness, e.g. due to cratering, causes thermal-infrared beaming: relative to a smooth surface, a rough surface displays more surface elements facing the Sun, even close to the limb, leading to a preferentially sunward emission and, for observations at low phase angle, a higher color temperature. Also, surface elements inside an indentation can radiatively exchange energy, leading to mutual heating.

Simple thermal models in which highly idealized assumptions are made on shape, thermal inertia, and surface roughness have enjoyed widespread usage over the past decades and have been shown to allow robust estimates of diameter and albedo in many cases (see Harris, 2006, for a recent overview).

Deriving the thermal inertia, on the other hand, requires more realistic thermophysical modeling, and in particular some knowledge of the object's spin

state, which is currently available for a small (but growing) number of asteroids only. Also, given the notorious difficulty of ground-based mid-IR observations, complex models with a large number of free parameters are not frequently warranted by the data quality. Nevertheless, detailed thermophysical models (TPMs) in which shape, spin state, thermal inertia, and surface roughness are explicitly taken into account, have been developed (e.g. Spencer, 1990; Lagerros, 1996, 1998; Mueller, 2007; Delbo' and Tanga, 2009) and have been used successfully to analyze mid-IR observations of asteroids (e.g. Müller and Lagerros, 1998; Harris et al., 2005, 2007; Mueller, 2007).

Since the thermal skin depth, a measure of the penetration depth of the heat wave, is typically in the cm-range, lateral heat conduction can be neglected. We also assume, as is common practice, that all relevant parameters are constant with depth and temperature.¹ It is then practical to use dimensionless units (see Spencer et al., 1989) for time t' , depth X , and temperature T' . The only free parameter in the heat conduction problem is then the thermal parameter Θ , as defined by Spencer et al., which is proportional to Γ . The equations governing thermal conduction into the subsoil are

$$\frac{\partial}{\partial t'} T'(X, t') = \frac{\partial^2}{\partial X^2} T'(X, t') \quad (2)$$

$$T'(0, t')^4 = \mu_S(t') + \Theta \frac{\partial}{\partial X} T'(0, t') \quad (3)$$

$$\lim_{X \rightarrow \infty} \frac{\partial}{\partial X} T'(X, t') = 0 \quad (4)$$

¹ In the case of lunar regolith, thermal parameters are actually empirically known to depend on both temperature and depth (see, e.g., Jones et al., 1975, and references therein). It is, however, unclear how to apply lunar results to asteroid regolith, which may be substantially different. Thermal-inertia results derived from TPMs should be thought of as effective averages over the relevant length scales.

where μ_S is the cosine of the local solar zenith distance (clipped to be ≥ 0). Eqn. 2 describes heat diffusion within the subsoil, eqn. 3 the surface boundary condition (thermally emitted energy equals absorbed solar energy plus the net heat flux from the subsoil), eqn. 4 ensures the regularity of the solution. See, e.g., Mueller (2007, Sect. 3.2.2) for a more detailed discussion.

Surface roughness can be modeled (following Spencer et al., 1989; Spencer, 1990) by multiplying surface temperatures as calculated from Eqns. 2–4 with a factor $\eta'^{-1/4}$ (η' is called β in the quoted papers). $\eta' < 1$ leads to elevated apparent color temperature. Increasing roughness leads to decreasing values of η' , a smooth surface would display $\eta' = 1$. Spencer et al. (1989) derive $\eta' \sim 0.72$ for the lunar surface.

5.1 *Binary TPM (BTPM)*

We describe a new Binary TPM (BTPM). It is based on the Spencer (1990) TPM, but includes the effect of mutual events (eclipses and occultations) on thermal fluxes. Our BTPM is limited to fully synchronized binary systems with a circular mutual orbit, such as Patroclus-Menoetius. Such objects are at rest in a co-rotating coordinate system. We can therefore use a single-body TPM to model the binary system, using a shape model which consists of two disjoint parts.

In contrast to most TPMs, which assume a globally convex shape, surface elements can now shadow one another and obstruct the line of sight toward the observer. In principle, some facets can also radiatively exchange energy, similar to mutual heating inside craters. That latter effect is not included in the

model. While it is important in the thermal modeling of globally non-convex bodies, it is negligible for eclipse observations at low solar phase angle.

When generating the binary shape model, both components are modeled as a mesh of triangular facets. Arbitrary component shapes are allowed by the model code; spheres and ellipsoids are used for this study. Each facet is checked for potential shadowers, i.e. other facets which appear above the local horizon. The list of potential shadowers along with details on the mutual viewing geometry is stored as part of the shape model (see Mueller, 2007, Sect. A.1.1 for details), ensuring that these calculations do not need to be repeated for each BTPM run.

Since mutual heating is neglected, the observable emission can be calculated facet-by-facet. Mutual heating would introduce an interdependence of surface temperatures and add to the complexity. Temperatures are calculated by numerically solving Eqns. 2–4. Eclipses are taken into account by setting μ_S , the insolation term in eqn. 3, to zero when the facet in question is eclipsed by another facet. Facets are considered eclipsed when their midpoint is shadowed (no partial shadowing of individual facets). Care must be taken to choose a sufficient time resolution, so as to provide appropriate resolution of eclipse events, which are short compared to the rotation period.

6 NEATM analysis

As a first step, the obtained spectra (minus the location of emissivity features) were analyzed using the NEATM (Harris, 1998). For the purposes of this study, it is useful to think of the NEATM as a simplified TPM in which

the shape is assumed to be spherical and thermal inertia is not directly modeled (therefore the spin state is irrelevant). It contains a model parameter η , which modifies model surface temperatures in the same way as our BTPM's η' (temperature $\propto \eta^{-1/4}$), but is used for an effective description of both surface roughness *and* thermal inertia. For observations at low phase angles, increasing thermal inertia lowers surface temperatures and therefore increases η (all other parameters kept constant).

The NEATM has been used widely to analyze thermal-IR observations of asteroids and is known to provide diameter results which are in generally good agreement with diameter determinations obtained using other methods. Additionally, conclusions on thermal properties such as thermal inertia can be drawn from the best-fit η value. See, e.g., Harris (2006) for a recent overview.

We fitted the NEATM to each of our 18 observations, see table 4 for the results. Since the NEATM does not include the effects of eclipses, it is not applicable during and just after eclipses. By averaging over observations 1.0, 1.7, 1.8, and 2.0–2.2 (see Fig. 2 and table 3), we obtain $D \sim 146$ km and $\eta \sim 0.85$. The η value indicates a relatively low thermal inertia and significant surface roughness, but does not provide a quantitative constraint on either.

While the NEATM takes no direct account of shadowing, the reduced total flux and the reduced temperature during and just after the eclipse events should be reflected in the NEATM results. Indeed, as can be seen in Fig. 5, there is a clearly recognizable dip in NEATM diameter during event 1 (results for event 2 are qualitatively identical), which reflects the event-induced flux drop. Simultaneously, the best-fit η rises, corresponding to a lower apparent color temperature due to the eclipse-induced cooling of the shadowed parts.

Table 4

NEATM fit to our Spitzer data: best-fit η , diameter D , and geometric albedo p_V .

Uncertainties were derived through a straight-forward Monte-Carlo analysis (mean and average of fits to 300 random spectra per observations, normally distributed about the measured data) and account for the statistical uncertainty, only.

Obs.	η	$D(\text{km})$	$p_V(\%)$	Obs.	η	$D(\text{km})$	$p_V(\%)$
1.0	0.845 ± 0.004	146.8 ± 0.5	4.34 ± 0.03	2.0	0.839 ± 0.004	148.5 ± 0.5	4.24 ± 0.03
1.1	0.852 ± 0.004	143.5 ± 0.6	4.54 ± 0.04	2.1	0.856 ± 0.004	144.9 ± 0.6	4.45 ± 0.04
1.2	0.864 ± 0.004	141.3 ± 0.5	4.68 ± 0.04	2.2	0.855 ± 0.005	143.4 ± 0.6	4.55 ± 0.04
1.3	0.860 ± 0.006	140.9 ± 0.7	4.71 ± 0.05	2.3	0.878 ± 0.005	141.5 ± 0.5	4.67 ± 0.04
1.4	0.856 ± 0.004	143.2 ± 0.5	4.56 ± 0.04	2.4	0.895 ± 0.006	138.9 ± 0.6	4.85 ± 0.04
1.5	0.848 ± 0.004	146.7 ± 0.6	4.34 ± 0.04	2.5	0.863 ± 0.004	133.6 ± 0.4	5.24 ± 0.04
1.6	0.827 ± 0.004	144.1 ± 0.6	4.50 ± 0.04	2.6	0.891 ± 0.004	142.5 ± 0.5	4.60 ± 0.04
1.7	0.835 ± 0.004	146.1 ± 0.5	4.38 ± 0.03	2.7	0.875 ± 0.004	144.1 ± 0.6	4.50 ± 0.04
1.8	0.851 ± 0.004	147.2 ± 0.5	4.32 ± 0.03	2.8	0.861 ± 0.004	143.3 ± 0.6	4.55 ± 0.04

While no quantitative conclusion on thermal inertia can be drawn from the NEATM analysis, our results indicate that we have indeed observed the thermal response to eclipse events.

Fig. 5. NEATM fits to observations 1.0–1.8 (see table 4). Above: Best-fit effective diameter against observing time. Below: Best-fit η against observing time. The vertical lines denote beginning and end of the eclipse event. The error bars are purely statistical.

7 BTPM analysis

7.1 Fitting technique

In this section, we describe fits to our Spitzer data (denoted as d_i for the data and σ_i for their uncertainties) using the new BTPM described in sect. 5.1. Variable parameters are Γ , η' , area-equivalent system diameter D_A , and the

time of the events (eclipse time predictions from the orbit model are currently uncertain by $\pm$ a few hours). To this end, synthetic lightcurves were generated using the observing geometry given in table 2 (separately for each event) and for a large range of Γ and η' values at those wavelengths λ_i at which Spitzer data have been obtained. The positions of emissivity features (10–12 and 18–22 μm , see sect. 4) were disregarded. Model fluxes $m_i(\lambda_i)$ were calculated for 1000 time points per revolution, corresponding to a time resolution of ~ 6 min or roughly the length of one Spitzer observation. This provides more than 40 time points across the duration of each ~ 4 h event. The rough rotational phase of the events was determined from visual inspection of the synthetic lightcurves, the exact timing was determined by fitting a time offset Δt . All model calculations were performed assuming $H = 8.19$, $p_V = 0.0433$, and $D_A = D_0 = 147$ km. Fluxes are assumed to be proportional to D_A^2 : $m_i(\lambda_i, D_A) = x m_i(\lambda_i, D_0)$ with $x = (D_A/D_0)^2$.² For each considered set of Γ , η' , and Δt the best-fit x is found by minimizing (through linear regression)

$$\chi^2 = \sum_i \frac{[x m_i(\lambda_i) - d_i(\lambda_i)]^2}{\sigma_i(\lambda_i)^2}. \quad (5)$$

The corresponding best-fit diameter equals $D_A = \sqrt{x} 147$ km.

After initial runs over wider and coarser grids, an equidistant grid was used with a step width of $0.5 \text{ J s}^{-1/2} \text{ K}^{-1} \text{ m}^{-2}$ in Γ , 0.0025 in η' , and 1 min in Δt . Data were analyzed separately for each event. For each combination of Γ , η' , and

² Implicitly, we neglect the albedo dependence of thermal fluxes: varying D_A with constant H varies p_V . Temperatures depend on the absorptivity, which is a strong function of p_V for high albedo, but a weak function for low p_V . Since Patroclus' albedo is very low, we reckon this approximation is uncritical (see also Harris and Harris, 1997).

Δt , the best-fit x and corresponding χ^2 were determined and stored. The grid was then searched for that combination of Γ , η' , and Δt which led to the global minimum in χ^2 .

In order to study the accuracy of the results, a Monte-Carlo technique was employed. For each observation, 5000 random ("noisy") spectra were generated; for each wavelength the distribution of the 5000 random points is Gaussian, with a mean value equal to the measured flux and a standard deviation equal to the flux uncertainty. Best-fit BTPM parameters were determined for each set of nine random spectra; mean value and standard deviation of the resulting values were adopted as nominal value and statistical uncertainty, respectively. This error analysis does not yet account for the uncertainty in the axis of the mutual orbit ($\lambda = 241.37 \pm 0.33^\circ$, $\beta = -57.35 \pm 0.36^\circ$; Berthier et al., 2007). Eclipse depth depends sensitively on the sub-solar latitude and therefore on the orbital axis, thus the axis uncertainty (while small) could be expected to have a significant impact on the accuracy of our thermal-inertia result. We repeated the Monte-Carlo BTPM analysis assuming the axis within the quoted range of uncertainty that leads to the largest change in sub-solar latitude: $\lambda = 241.70^\circ$, $\beta = -57.71^\circ$. The offset axis leads to a somewhat increased sub-solar latitude, implying shallower eclipse events, i.e. a smaller area fraction of the eclipsed component is shadowed.

Additional simulations were performed in which the components were assumed to be prolate spheroids with aligned long axes (nominal orbit solution). Axis ratios (identical for the two components) of up to 1.09 were tried; larger ratios would be inconsistent with the low visible lightcurve amplitude (see sect. 2).

Table 5

Best-fit BTPM parameters for events 1 and 2. The two lines of results per event refer to the nominal orbit solution and that offset by 1σ (see text), respectively. Syzygy times are as seen on Spitzer. There are $9 \times 178 = 1602$ data points per event and four fit parameters, hence a best-fit χ^2 in the low thousands is to be expected.

	Syzygy	χ^2	Γ	η'	$D_{\mathcal{A}}$
	($JD - 2453910$)	($\text{J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$)			(km)
Event 1	1.466 ± 0.003	2543 ± 84	20.7 ± 3.8	0.762 ± 0.014	145.7 ± 0.3
	1.470 ± 0.002	2586 ± 84	7.6 ± 1.7	0.814 ± 0.008	146.0 ± 0.3
Event 2	3.624 ± 0.001	3566 ± 102	6.4 ± 0.9	0.838 ± 0.005	143.4 ± 0.3
	3.624 ± 0.001	3847 ± 109	5.1 ± 0.8	0.845 ± 0.004	143.1 ± 0.3

7.2 Results

BTPM results are reported in table 5 for both the nominal and the offset axis. Results from the ellipsoidal-shape model runs are indistinguishable and are not reported.

The best-fit diameter values resulting from the four BTPM analyses and the NEATM analysis (~ 146 km; see sect. 6) are mutually consistent at the 1 % level and average to 144.6 km.

The time of the syzygy (maximum eclipse depth, when the two components and the Sun are aligned) was fitted to the data and is consistent with the Berthier et al. (2007) model prediction within the uncertainty of $\pm$ a few hours. The times given in table 5 are for a Spitzer-centric system; subtract

the one-way light-time for the corresponding times at Patroclus.

Model runs with the offset axis lead to lower thermal-inertia results in both cases. This is expected since the offset reduces the eclipse depth: The leading-order effect of increasing thermal inertia or decreasing eclipse depth is to reduce the eclipse-induced flux drop; hence underestimated eclipse depth leads to underestimation of thermal inertia. Final error estimates are obtained by adding in quadrature the statistical uncertainty in the nominal solution to the difference between the nominal and offset-axis solutions; our final results are $\Gamma = 21 \pm 14 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ (event 1) and $\Gamma = 6.4 \pm 1.6 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ (event 2).

While our two thermal-inertia results differ by a factor > 3 , they are mutually consistent given the uncertainties. Note, however, that neither result is representative of the system as a whole, but is dominated by the respective shadowed region. A difference between the two thermal-inertia results would therefore imply inhomogeneous regolith properties and might hint at component-to-component differences. While tantalizing, our data do not allow this conclusion to be drawn at a statistically significant level. We estimate the system-average thermal inertia to be between 5 and 35 $\text{J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ or $20 \pm 15 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$, where the scatter may be partially due to surface inhomogeneity.

Our thermal-inertia results depend sensitively on the assumed spin axis, as evidenced by our experiment with the offset axis and, more drastically, by our experience with preliminary orbit models. E.g., in a preliminary data analysis based on a preliminary orbit model (Mueller, 2007, Sect. 6.8), a best-fit Γ of $\sim 90 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ was obtained. The uncertainty introduced by the spin-axis uncertainty was not studied in the previous analysis. We point out, however,

that the new orbit model fits the Spitzer data much better: χ^2 is now reduced by a factor > 3 and is now in the expected range given the number of data points. Also, the nominal spin axis fits the Spitzer data better than that offset by 1σ , inspiring further trust in the presented results.

The best-fit η' ranges from 0.76 to 0.85, between the lunar value of $\eta' \sim 0.72$ (Spencer et al., 1989) and the NEATM best-fit $\eta \sim 0.85$, which describes the (cooling) effect of thermal inertia in addition to roughness. The best-fit η' is inversely correlated with best-fit Γ . The impact of thermal inertia on surface temperatures is twofold: It changes the response to the eclipse (i.e. depth, shape, and wavelength dependence of the eclipse-induced flux drop), but it also determines the diurnal temperature distribution and therefore the overall spectral shape (color temperature). As will be discussed in the next section, the effective thermal inertia for these two phenomena need not be the same because of the different time and depth scales involved. Our model, however, assumes a homogeneous thermal inertia. Due to the design of our observations, the data analysis is more sensitive to the eclipse effect than to the diurnal effect; we take the variation in best-fit η' to be an effective description of the residual diurnal effect rather than an indication of roughness inhomogeneity.

8 Discussion

8.1 Thermal inertia

Our thermal-inertia result is below the value for lunar regolith ($50 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$), suggesting a very fine regolith and dearth of rocky outcrops. For a meaningful comparison, however, the lower temperatures at a heliocentric distance of

$r \sim 6$ AU must be taken into account: For predominantly radiative heat transfer, as expected in a fine regolith on an airless body, the thermal conductivity κ scales with T^3 , hence

$$\Gamma \propto \sqrt{\kappa} \propto T^{3/2} \propto r^{-3/4}. \quad (6)$$

The thermal inertia of Patroclus ($20 \pm 15 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ at 5.95 AU) scaled to $r = 1$ AU is around $76 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$, comparable to the lunar value and suggesting a similarly fine regolith.

Our result is similar to published upper limits on the thermal inertia of two other Trojans (Fernández et al., 2003, see also table 6) which were, however, based on a significantly less extensive database and a highly indirect method. We are not aware of any other thermal-inertia determination of Trojans.

Table 6 contains a list of published thermal-inertia values for Jovian satellites, which are at the same heliocentric distance as Patroclus. Two values are given for Io, Ganymede, and Callisto, respectively, based on ground-based eclipse observations (first line) or on thermal imaging of the diurnal temperature distribution from near-by spacecraft (second line). The latter are effective disk-average values; significant thermal-inertia inhomogeneity was found across the surfaces of the satellites. Patroclus' thermal inertia is roughly in line with the satellites' eclipse thermal inertia, which is lower than their diurnal thermal inertia by a factor of several. Different explanations for this difference in the satellites have been published; Greeley et al. (2004) review two mechanisms which require significant amounts of surface ice, and a third mechanism (first proposed by Morrison and Cruikshank, 1973) based on vertical thermal-inertia inhomogeneity: Because eclipse events are much shorter than the spin period, the corresponding thermal wave penetrates much less deep. Keeping in mind

Table 6

Thermal-inertia measurements of Trojans (top 3 lines) and Jovian satellites (below).

	Thermal inertia ($\text{J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$)	Method	Reference
(617) Patroclus	20 ± 15	eclipse	this work

	~ 50	diurnal	Spencer (1987), Moore et al. (2004)

that the TPM ‘thermal inertia’ is really an average over the relevant depth scale (see footnote 1 on p. 24), the effective diurnal thermal inertia is averaged over deeper regions than its eclipse counterpart. The thermal-inertia difference then implies that near-surface material has a lower thermal inertia than the material underneath (at cm depths), consistent with expectations that the most under-dense and ‘fluffiest’ material is located on top of more compact material. Such vertical grain-size sorting has been observed directly in the

lunar regolith during the *Apollo* era.

For Patroclus, we do not have a measurement of the diurnal thermal inertia, but the eclipse thermal inertia is similarly low. No evidence of surface ice has been found in the spectra of Patroclus (Emery and Brown, 2003, 2004), hence the two ice-based mechanisms to increase the diurnal thermal inertia do not apply. A measurement of the diurnal thermal inertia, combined with our result, would therefore allow depth-resolved information to be obtained to some extent.

While comparisons with the Galilean satellites are instructive, we caution that Patroclus is smaller than the satellites by more than an order of magnitude. For an asteroid sample ranging from sub-km near-Earth asteroids to (1) Ceres, Delbo' et al. (2007) found a trend whereby larger objects have lower thermal inertia. Mueller et al. (2006) and Delbo' and Tanga (2009) report constraints on the thermal inertia of $D \sim 100$ km main-belt asteroids (Lutetia, Lydia, Ekard), similar to Patroclus in size. While the uncertainties are large, $\Gamma \sim 100 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ appears to be a typical value in this size range. Using eqn. 6, this corresponds to $\Gamma \sim 60 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$ at $r \sim 6$ AU, significantly above our result but consistent with the diurnal thermal inertia of the Galilean satellites. This is consistent with either a systematically finer regolith on Patroclus (it is unclear what could cause this) or the above-mentioned vertical grain-size sorting.

8.2 Diameter and mass density

The diameter results from two independent data analyses (NEATM and BTPM) agree at the 1 % level and average around $D_A \sim 145$ km for the area-equivalent diameter of the system as a whole: $D_A^2 = D_1^2 + D_2^2$. The statistical diameter uncertainty is negligible relative to the systematic uncertainty, although the latter is hard to estimate. Since it is more realistic, the BTPM would be expected to have lower systematics. While more work is required to accurately gauge the systematic uncertainty in TPM-derived diameters, it was found not to exceed 10 % in the case of near-Earth asteroids (see Mueller, 2007). Due to its more regular shape and the low phase angle of our observations, Patroclus is less challenging to model than near-Earth asteroids. We conclude that 10 % is a conservative upper limit on the diameter uncertainty, corresponding to 20 % in albedo (see eqn. 1). Our final results are: $D_A = 145 \pm 15$ km and $p_V = 0.045 \pm 0.009$.

Our result is intermediate between previous estimates: Tedesco et al. (2002) obtained 140.9 ± 4.7 km (assuming $\eta = 0.756$), and Fernández et al. (2003) obtained 166.0 ± 4.8 km (assuming $\eta = 0.94$). The quoted error bars are purely statistical. We point out that their results were subject to significant systematic uncertainties due to the assumed (not fitted to the data) η values. Systematic uncertainties are acknowledged by Fernández et al. to limit the accuracy of their results, but no quantitative discussion is given. Since our database has a significantly larger wavelength coverage and since we use a more realistic thermal model, the true uncertainty in the cited diameters should be large compared to that in our results. With this in mind, all diameter results are in reasonable agreement with one another.

Assuming a diameter ratio of $D_1/D_2 = 1.082$, the components' diameters are $D_1 = 106 \pm 11$ and $D_2 = 98 \pm 10$ km. The corresponding bulk density is 1.08 ± 0.33 g cm⁻³, in excellent agreement with the Berthier et al. (2007) result of $0.90^{+0.19}_{-0.33}$ g cm⁻³ and indicative of a bulk composition dominated by water ice. Significant contributions by heavier materials (such as rock) are possible if compensated by interior voids. Near-infrared spectra show no indication of water ice on the surface, even in the 3 μ m region, where even very small amounts of H₂O would be detected (Emery and Brown, 2003, 2004). If the bulk composition does include significant H₂O, the surface must be coated by a devolatilized mantle. This would be expected for an extinct-comet-like object, i.e. an icy object that spent significant amounts of time in the inner Solar System.

It is not unusual for published asteroid diameters to be quoted with purely statistical uncertainties, neglecting the typically dominant systematics. Most known asteroid diameters are derived from thermal-infrared observations. While more research is needed to quantify their systematic diameter uncertainty, 10 % seems to be an appropriate value, larger when the color temperature is assumed rather than fitted to the data, as is typically done in the widely used 'Standard Thermal Model' (STM). This includes the entire SIMPS catalog (Tedesco et al., 2002), i.e. the majority of currently known asteroid diameters.

A realistic evaluation of the size uncertainty—including systematics—is crucial when published diameters are used to determine the mass density. Due to the dependence on D^{-3} , density uncertainties are frequently dominated by that in diameter. Ignoring the systematic diameter uncertainty may lead to overly optimistic density estimates. A diameter uncertainty of 10 % translates into 30 % in density; 15 % in diameter means some 45 % in density.

8.3 Mineralogy

It is instructive to compare Patroclus to its mythological antagonist, (624) Hektor, the only other currently known Trojan binary and the only other Trojan with known mass density.

Patroclus and Hektor have nearly identical albedo and mid-IR emissivity spectra, yet their densities differ by a factor > 2 : $\rho \sim 2.2\text{--}2.5\text{ g/cm}^3$ for Hektor (e.g. Weidenschilling, 1980; Marchis et al., 2006b; Lacerda and Jewitt, 2007) to Patroclus' $\rho \sim 1\text{ g/cm}^3$. Reflectance spectra of both are featureless from ~ 0.3 to $4.0\text{ }\mu\text{m}$, but Hektor displays a much steeper spectral slope throughout that wavelength range. It is uncertain whether the difference in spectral slope indicates distinct surface compositions or is a manifestation of differences in, e.g., grain size, abundance of opaque materials, or degree of space weathering.

Trojans in general form two distinct groups based on visible and near-IR colors and slopes (Szabó et al., 2007; Emery et al., 2007; Melita et al., 2008; Roig et al., 2008), one group similar to Hektor and one similar to Patroclus. It is tempting to take the density difference between Patroclus and Hektor as indicating a compositional difference between the two groups. In the light of this, their very similar mid-IR spectra are intriguing.

The mutual orbits of the Patroclus and Hektor systems are conspicuously dissimilar: While Patroclus is a double-asteroid system with two components of roughly equal size and nearly spherical shape, Hektor consists of a large irregular primary (which is thought to be a contact binary itself) and a much smaller moonlet (Marchis et al., 2006b).

9 Conclusions

Patroclus Patroclus has a low thermal inertia of $20 \pm 15 \text{ J s}^{-1/2}\text{K}^{-1}\text{m}^{-2}$. This first thermal-inertia measurement for a Trojan indicates a surface covered in fine, mature regolith similar to large main-belt asteroids and the Galilean satellites. Independent evidence for a fine regolith is provided by the mid-IR emissivity features reported herein, which imply the presence of very fine silicate grains on the surface.

Patroclus' optical lightcurve implies a nearly spherical shape for both components and indicates that the system is fully synchronized, probably due to tidal component-component interactions.

We confirm that Patroclus' albedo is low ($p_V = 0.045 \pm 0.009$) and that the system's bulk mass density is $1.08 \pm 0.33 \text{ g cm}^{-3}$. Patroclus' known physical properties (albedo, density, fine silicate regolith, and published optical spectra which are similar to cometary surfaces but devoid of any traces of water ice) match those expected in extinct comets and suggest that Patroclus formed beyond the 'snow line' but spent significant amounts of time in the inner Solar System, leaving its surface devolatilized. Such a dynamical history is expected for Trojans in the framework of the 'Nice Model' (Morbidelli et al., 2005, 2009). While Patroclus is arguably the best-studied Trojan asteroid, it is unclear how representative it is for the Trojan population as a whole; the composition of the only other Trojan with known mass density, Hektor, is dominated by materials heavier than water ice.

Binary eclipses in the thermal infrared We demonstrate the viability of a new method to measure the thermal inertia of asteroids, through thermal observations during and after shadowing events in binary systems. This new method is considerably more direct than the usual method of sampling the diurnal temperature distribution through observations at a large phase-angle range.

In either case, the measured thermal inertia is an effective average over the relevant depth scale, which is smaller for eclipses than for rotation due to the shorter time scales involved. Vertical grain-size sorting may cause the eclipse thermal inertia to be lower than the diurnal thermal inertia. While this makes comparisons harder, it may shed light on the elusive vertical regolith structure.

For objects in the outer Solar System, sufficient phase-angle coverage for the diurnal measurement method is hard or impossible to obtain. The maximum phase angle $\alpha_{\max}$ decreases with increasing heliocentric distance r (in AU): $\alpha_{\max} = \arctan(1/r)$. For Neptune, e.g., $\alpha_{\max} \sim 2^\circ$. Thermal eclipse observations may be the only method to measure the thermal inertia of Centaurs and Kuiper Belt objects from (close to) Earth – once the mutual orbits of such binary systems are reliably known.

10 Acknowledgments

We wish to thank Petr Pravec for helping develop this project. Enlightening discussions with John Spencer (and a great mountain hike!) are gratefully acknowledged. This work is based on observations made with the Spitzer Space Telescope, which is operated by the Jet Propulsion Laboratory, California

Institute of Technology under a contract with NASA. Support for this work was provided by NASA through an award issued by JPL/Caltech. The work of M.M. is supported through JPL/Spitzer contract #1287372. The work of F.M. is supported by the National Aeronautics and Space Administration issue through the Science Mission Directorate Research and Analysis Programs number NNX07AP70G & NNG05GF09G
